Theoretical modeling is presented for a freestanding vitreous silica bilayer which has recently been synthesized and characterized experimentally in landmark work. While such two-dimensional continuous random covalent networks should likely occur on energetic grounds, no synthetic pathway had been discovered previously. Here the bilayer is modeled using a computer assembly procedure initiated from a single layer of a model of amorphous graphene, generated using a bond-switching algorithm from an initially crystalline graphene structure. Each bond is decorated with an oxygen atom and the carbon atoms are relabeled as silicon, generating a two-dimensional network of corner-sharing triangles. Each triangle is transformed into a tetrahedron, by raising the silicon atom above each triangular base and adding an additional singly coordinated oxygen atom at the apex. The final step in this construction is to mirror-reflect this layer to form a second layer and attach the two layers to form the bilayer.

We show that this vitreous silica bilayer has the additional macroscopic degrees of freedom to form easily a network of identical corner-sharing tetrahedra if there is a symmetry plane through the center of the bilayer going through the layer of oxygen ions that join the upper and lower monolayers. This has the consequence that the upper rings lie exactly above the lower rings, which are tilted in general. The assumption of a network of perfect corner-sharing tetrahedra leads to a range of possible densities that we characterize as a flexibility window, with some similarity to flexibility windows in three dimensional zeolites. Finally, using a realistic potential, we have relaxed the bilayer to determine the density and other structural characteristics such as the Si-Si pair distribution functions and the Si-O-Si bond angle distribution, which are compared with experimental results obtained by direct imaging.

I. INTRODUCTION

The continuous random network model of network glasses is widely accepted as a model for materials such as vitreous silica and amorphous silicon. Although it has been more than eighty years since Zachariasen proposed this model of glasses and experimental evidence has been compelling over the years, especially through diffraction experiments, it has never been quite conclusive since the probability distribution of rings of various sizes has been elusive to determine explicitly experimentally. This situation has now changed dramatically with the discovery and imaging of two-dimensional bilayers of vitreous silica. Here, not only the distribution of rings but the actual detailed atomic ring structure has been imaged for the first time in real space, removing all speculation from this subject (at least for this class of materials). These are the first examples of which we are aware of real-space imaging of a random network and as such represent tours de force. Previously only small defect patches have been imaged, as for example for graphene as reported by Geim.

In this paper, we provide an atomic level computer model for a vitreous silica bilayer and demonstrate some intriguing and unexpected features that are shown to agree with experiment. There is a symmetry plane through the center of the bilayer where all the oxygen atoms that connect the tetrahedra in the lower and upper planes of the bilayer lie. Each tetrahedron comprises an SiO$_4$ unit and the whole bilayer is a perfect corner-sharing continuous random network with the same chemical formula SiO$_2$ as 3d bulk vitreous silica. Each monolayer is amorphous with rings from 4 up to about 9 in size, consistent of course with Euler’s theorem that the average ring size is 6. Because of the amorphous nature of the monolayer and the need for oxygen bridges connecting the upper and lower layers, it is necessary for the two layers to have the same ring structure and be topologically identical to form a complete corner-sharing tetrahedral network. The result that the two layers are also geometrical mirror images of each other is quite surprising at first sight in a system that is a priori without any symmetry, but comes about from understanding the nature of the constraints within the network as explained later. This is consistent with our detailed atomic modeling and also is in accord with the experimental results which show that the upper and lower layers do lie one on top of the other.
as required by a symmetry plane. We note that this does not imply that there is a threefold axis between the two upper and lower tetrahedral units (tetrahedral pair) through the common central oxygen atom; rather this Si-O-Si angle through the central oxygen has a distribution of values throughout the sample, as do all the other Si-O-Si angles in the bilayer.

Thin vitreous SiO2 films have been grown on Mo(112),6 Ru(0001),3,7,8 and graphene,4 the last two examples interpreted as bilayers. Figure 1 shows the experimentally obtained ring statistics from Refs. 3 and 4. A key observation is that the ring statistics obtained from the two experimental samples are not the same, although this is not surprising in view of their different preparation conditions, analogous to various fictive temperatures used to characterize the preparation conditions for bulk silica.9 Different Monte Carlo annealing temperatures and/or protocols used computationally to create vitreous silica bilayers also lead to different ring statistics, similarly to those documented previously in amorphous cellular networks10 and in amorphous graphene.11

What is unclear is the extent to which these differences in ring statistics reflect the finite system sizes under study or the more complex and more interesting dependence of the structure on the precise preparation conditions (including the nature of the substrate). The ring statistics are a fundamental quantity and their dependence on sample size imaged and on preparation conditions will be an important area for future study, especially experimentally. The simplest nontrivial (second cumulant) measure of the ring statistics $\mu_2$ should be related to the static structure factor $S(0)$, as in bulk vitreous silica.9

Recent simulation work, in which amorphous graphene (a-G) configurations were generated using both bond-switching Monte Carlo and molecular dynamics methods, highlights how networks constructed primarily from 5-, 6-, and 7-membered rings may adopt a range of structures.11 A useful simple metric for distinguishing between the different samples is the second moment of the ring size distribution,

$$\mu_2 = \langle n^2 \rangle - \langle n \rangle^2,$$

where $\langle n \rangle$ is the mean ring size for an ideal two-dimensional network constructed from purely three-coordinated sites ($\langle n \rangle = 6$ from Euler’s theorem). This metric conveniently captures the major changes in ring statistics from sample to sample in a single number. The values of $\mu_2$ for the experimental data presented in Fig. 1 are 0.904 and 0.886 (from Refs. 3 and 4, respectively).

II. FLEXIBILITY WINDOW

A key concept that will emerge is that there is a flexibility window involving $O(N)$ motions among the rigid corner-sharing tetrahedra. This flexibility window designates a range of densities over which a framework of rigid tetrahedra, freely jointed at all corners with a given topology, can exist. The low-density end of the window is defined by the maximum extension the framework can sustain without breaking apart, and the high density end of the window is determined by oxygen-oxygen overlap between adjacent tetrahedra. We will see that when additional terms are included in the potential, particularly the Coulomb terms, a particular density is selected from within the flexibility window. Similar ideas have been explored extensively in zeolites12 where the origin of the window is also due to symmetry. However, in bulk zeolites the symmetry is associated with the rotations and translations of the unit crystallographic cell, whereas here the symmetry is due to a reflection symmetry, that is maintained between two monolayers that comprise the bilayer. We will return to a full analysis of this latter point in a later section.

III. CONSTRUCTION METHOD

The initial SiO2 bilayer configurations are generated from ideal a-G coordinates (Fig. 2), which were themselves generated using a “bond-switching” Monte Carlo algorithm (as described, for example, in Ref. 11; see also Ref. 10). The a-G configurations generated in this manner are guaranteed to be constructed exclusively from three-coordinated carbon local environments. This method is superior to others in the sense that it produces no coordination defects or dangling bonds, and is periodic with a supercell whose size can be chosen and varied. Seed a-G configurations were constructed with a range of different ring statistics and hence $\mu_2$ values. Several different network sizes were employed. For convenience we shall refer to these systems below by their sizes, $N = 120, 200, 400, 432$ [two configurations, distinguished as (a) and (b)], 834, 836, and 1792 atoms. The two configurations containing 432 carbon atoms are generated with different ring statistics to give some extra perspective on the effect of the ring distribution on physical properties. Table I lists the values of $\mu_2$ for these a-G configurations, while Fig. 1 shows the detailed ring size distributions for these computer-generated structures.

The method for generating the bilayers is motivated by the observation that the two layers sit on top of each other. As a result, each layer can be generated from the a-G configuration and joined with oxide anion bridges. To generate the initial SiO2 bilayer configurations, each carbon atom is transformed...
FIG. 2. (Color online) The freestanding vitreous silica bilayer is modeled by first creating an amorphous graphene layer from a crystalline graphene sheet through a bond-switching algorithm (top panel), where the carbon atoms are shown as solid black dots. An oxygen ion is then placed at the center of each carbon-carbon bond, forming a network of corner-sharing triangles (second panel), and the carbon is replaced by a silicon ion. The silicon atom is then lifted out of the plane and an oxygen ion (shown as a solid red dot) is placed above this silicon to form a tetrahedron. This silica monolayer is mirror inverted and placed directly above the first monolayer (third panel) shown in plan view. Finally these two monolayers are brought together to form the silicon bilayer (fourth panel) in which the central oxygen ions are combined to make single bridging oxygen ions between the two monolayers.

TABLE I. Variances $\mu_2$ in the second moment of the ring size distribution for the eight configurations studied here, labeled by the number $N$ of atoms in the original graphene layers, or equivalently the number of Si atoms in a monolayer. The resulting bilayer therefore has $2N$ SiO$_2$ units. Also shown are the two experimentally observed configurations.

with all unshared corners pointing up. The second layer of the bilayer is created by producing a mirror image of the first layer (such that the tetrahedra are now pointing in the down direction) and offsetting the layer along the $z$ direction, to lie above the first bilayer; see Fig. 3. Finally, the median oxygen atoms are coalesced between the two layers giving the required SiO$_2$ bilayer stoichiometry. The system supercell lengths are then rescaled so as to generate the required Si-O bond lengths. As a result, the systems considered contain $2N$ [$=240, 400, 800, 864(a), 864(b), 1668, 1672, and 3584$] SiO$_2$ molecules.

These structures are relaxed using standard molecular dynamics (MD) procedures with appropriate model inter-ion potentials. Two forms of potential model are considered. The first, which we will refer to as the harmonic potential, is designed to produce a corner-sharing network of identical regular tetrahedra, with freedom of the individual tetrahedra to move and tilt with respect to each other while maintaining the topology. This allows for hinging freedom of the joined tetrahedral corners, and does not impose reflection symmetry. A convenient way to accomplish this is to use harmonic springs to join the four nearest-neighbor Si-O and six nearest-neighbor O-O atoms in individual tetrahedron. Computationally the ratios of the O-O and Si-O equilibrium bond lengths of the potentials are chosen so as to produce ideal tetrahedra in isolation; thus the equilibrium separation for the neighboring oxygens along the edge of the tetrahedron in the O-O potential is taken to be $\sqrt{8/3} \approx 1.633$ times that for the Si-O nearest-neighbor separation. For computational convenience the spring force constants are taken to be equal for both the Si-O and O-O pairs within each tetrahedron. The detail of this interaction is only significant in the sense of allowing for a relatively rapid energy minimization.

These simple harmonic potentials do not however preclude different tetrahedra from overlapping, as would be the case in reality, for example to prevent oxygen overlap, and as limits the motions in zeolites. In order to prevent this in a computationally convenient manner, the harmonic potential is augmented with a purely repulsive potential which acts between pairs of silicon atoms effectively acting as an
FIG. 3. (Color online) Showing the structure of the bilayer made of perfect corner-sharing tetrahedra from various perspectives, relaxed with the harmonic potential and with a dimensionless area of \( A^* = 0.9 \). This puts the structure into an arbitrary place in the flexibility window at some density (not restricted to the experimental density). This illustration is a piece from a bilayer with a periodic supercell with 864 silicon atoms. Notice that the central oxygen atoms all lie in the symmetry plane. Each tetrahedron has four oxygen ions shown as small red spheres at the vertices and a silicon ion at the center.

inter-tetrahedron repulsive term. The physically more realistic imposition of a short-range repulsion between oxygen atoms requires greater computational accounting. The chosen form is a shifted 24-12 potential,

\[
U(r) = 4\epsilon \left( \left( \frac{\sigma}{r} \right)^{24} - \left( \frac{\sigma}{r} \right)^{12} \right) + \epsilon, \tag{2}
\]

where \( \sigma \) is the atom diameter and \( \epsilon \) is the well depth of the (unshifted) potential. The potential is cut off at the minimum \( r_{\text{min}} = (2)^{1/12} \sigma \) while ensuring continuity in both energy and force. The parameter \( \epsilon \) is fixed while \( \sigma \) can be varied to explore the extent of the flexibility window. In the second form a more realistic potential model (a TS potential)\(^{13}\) is used in which pairwise-additive potential energy terms (including ion-based charge-charge electrostatic interactions) are augmented with a description of (many-body) polarization effects.\(^{13-15}\) This potential is more realistic than the harmonic potentials plus repulsions, mainly because Coulomb terms are included which are known to be important in ionic materials,\(^{12}\) and we use it for a further optimization of the bilayer structure. Nevertheless the harmonic potential plus repulsions is useful as the language of flexibility windows and constraints and the symmetry plane can be used, as is discussed in the next section.

We believe the choice of potential model is not crucial in displaying potentially interesting phenomenology in systems of this type. The harmonic potential is chosen as (arguably) the simplest model which constrains the system to form a series of ideal linked tetrahedral units. The TS potential is chosen as a potential which accounts well for a number of key (bulk) properties whilst retaining a relatively simple functional form.

Anion polarization, which controls the Si-O-Si bond angles in models of this type, may be crucial in defining the structures adopted both for silica and (potentially) other chemically-related systems. While the structures formed are low dimensional, the atoms retain their full (bulk) coordination so it is reasonable (at least in the first approximation) to apply potentials derived by reference to bulk three-dimensional properties. These will most probably need further refinement as more precise experimental results on the vitreous silica bilayers become available.

We are very concerned with variation of the number density (number of SiO\(_2\) molecules per unit area) or, equivalently, the area occupied by a single molecule. The number density \( n_0 \) is expressed in terms of SiO\(_2\) units per unit area projected onto the central plane of the bilayer, while the area \( A \) is expressed by reference to an ideal value \( A_0 \) which is the area occupied by a crystalline sample, based on crystalline graphene, in which all the tetrahedral pairs are aligned vertically with a threefold axis about the central oxygen ion, and which would be obtained from bilayers constructed from an ideal crystalline graphene sheet containing only six-membered rings.

Energy minimizations are performed over a range of dimensionless reduced areas \( A^* = A/A_0; 0.4 \leq A^* \leq 1.4 \). Note that \( A^* = 1 \) is the maximum possible area which can be attained without strain (i.e., distortion within the individual tetrahedra). At each density, the system’s energy is minimized using a steepest descent method. The atom positions are allowed to evolve, controlled by standard Newtonian mechanics, and the velocities are reset to zero (quenching the kinetic energy) when the kinetic energy reaches a (local) maximum. In order to allow explicitly breaking of the initial imposed reflection symmetry between the bilayers, several simulations are performed with randomized starting locations.

IV. RESULTS

In Fig. 4, we show comprehensive results for the harmonic and the TS potential. These results are given for two different samples (derived from the 200 and 432a atom a-G samples, so containing a total of 1200 and 2592 atoms, respectively) in the two panels to give some perspective on the universality of the results. These two configurations are chosen as examples of systems with relatively high and low ring distribution variances (Table I). The results for the harmonic potential that describes the corner-sharing network of rigid tetrahedra are shown by the red, blue, and green lines and show a distinct flat region for both samples that is the manifestation of the flexibility window. These three curves are generated by different values of \( \sigma \), with the smaller values of \( \sigma \) leading to larger flexibility windows.
The flexibility window exists over a similar range of densities for both samples. It should be noted that the high-density limit of the flexibility window is defined by repulsive potentials of the Si ions in this model, rather than the more physical repulsion between the larger O ions that is expected physically. The low-density limit, defined as the lowest the density can be without breaking the network of corner-sharing tetrahedra, is where almost all zeolites are found experimentally. This is because when a more realistic potential than the harmonic potential is used, Coulomb inflation maximizes the pore volume, and hence the sample volume.\(^\text{12}\) The high-density limit in zeolites is determined by that density at which interpenetration of the oxygen atomic spheres would onset. A similar situation is found here for vitreous silica bilayers, with a well-defined flexibility window. This is in contrast to the case of three-dimensional vitreous silica (no pores) where the flexibility window collapses to a single point (single density) even with only the linked-tetrahedral constraints.\(^\text{12}\)

Figure 4 also shows the energies obtained by minimizing the energy of the 400 and 864 SiO\(_2\) molecular bilayers using the TS potential. The energies resulting from the use of this potential function show sharp minima (when plotted on a logarithmic scale used here). These potentials produce a unique conformational minimum just below the high area limit of the flexibility window (obtained with the harmonic potential).

On the other hand, for both these configurations the energy minima for the TS potential do lie within the currently observed experimental density range (\(n_0 = 18.4\) and 20.0 SiO\(_2\)/nm\(^2\) for the 400 and 864 molecule configurations, respectively). The higher densities possible using the harmonic potential compared to the TS are to be expected due to the lack of electrostatic interactions which act to push the silicon cations apart. It is significant to note that the two configurations studied in depth produce energy minima with the TS at different densities, implying the optimal density to be a function of the atomistic detail (ring structure) of the bilayer configuration.

Figure 5 shows the Si-Si radial distribution functions (RDFs) obtained for both the harmonic and TS potentials for both the 400 and 864 molecule configurations. The RDFs are calculated by projecting the Si-Si separations onto the xy plane (and hence mimicking the experimental procedure). Energy minimization using the TS potential produces structures with order beyond the nearest-neighbor length scale of the same form as that generated by the harmonic potential. The first peak (corresponding to the nearest-neighbor Si-Si length scale) appears considerably sharper for the TS potential, reflecting the ordering imposed by the presence of the electrostatic interactions. The reduced intensities in the 864 molecule system compared with the 400 molecule one reflects the higher degree of disorder in the former (as characterized by their respective values of \(\mu_2\)).

Figure 5 also shows the experimentally determined functions (from Ref. 16) obtained for both a crystalline and an amorphous section of bilayer. The analysis of the experimental data remains very preliminary, and a much better determination of the density will be possible once larger areas of the samples are imaged. For the moment the fairly wide estimates of the experimental density\(^\text{16}\) are shown by the yellow lines in Fig. 4. These wide estimates are obtained from the relatively small field of view of the vitreous silica bilayers currently available, and we await larger fields of view from which a more accurate density can be obtained. Note this density is obtained directly from the atomic imaging.\(^\text{16}\) The density is a very important parameter to know, both in regards to the
experimental areas should discriminate between the nuances of the model structures in this paper, and data from much larger bulk glass (BADs) determined for the harmonic potential (at 0.500 and 1.046) using the harmonic (black lines) and TS potential (blue lines). Successive functions are offset along the ordinate axes for clarity. In each case the lower curve is for the 400 molecule configuration and the upper for the 864 molecule case. The original carbon RDF determined from the a-G sample is also shown (red). This function has been scaled along the abscissa in terms of the first peak positions for comparison. The harmonic potential functions are obtained at a density of 0.81 (at which the energy can be quenched) while the TS functions are obtained at the respective energy minima. The uppermost curves are the amorphous (magenta) and crystalline (cyan) functions obtained from experiment (Ref. 16).

The change in the peak position in the bond angle distribution shows a major peak at $\theta \sim 125^\circ$ of width $\Delta \theta \sim 25^\circ$ while the TS shows a peak position (width) of $\theta \sim 132^\circ$ ($\Delta \theta \sim 15^\circ$). Note that the removal of anion polarization terms from the TS potential (to generate a rigid-ion model) results in a peak position (width) of $\theta \sim 150^\circ$ ($\Delta \theta \sim 10^\circ$). The change in the peak position in the bond angle distribution is consistent with the inclusion of anion polarization which acts to effectively screen the Si-Si (repulsive) electrostatic interactions and hence stabilizes more acute Si-O-Si bond angles. The distribution appears very different from that obtained for the bulk glass using the TS potential (Ref. 17) also shown in Fig. 6(a) which shows a broader distribution ($\Delta \theta \sim 50^\circ$) with a peak at $\theta \sim 150^\circ$ consistent with experiment. Note that in an unrelaxed crystalline bilayer, based on a crystalline graphene seed with a median symmetry plane, the Si-O-Si bond angle is $\cos^{-1}(7/9) \approx 142^\circ$ within a monolayer and $180^\circ$ between monolayers. It is interesting to note that $142^\circ$ is very close to the chemically preferred Si-O-Si bond angle in the absence of any topological strains due to rings. The component at lower angles in the middle blue panel in Fig. 6(a) is associated with in-plane angles and the other peak with angles involving both planes. In the other two panels in Fig. 6(a), there is only a single very broad peak.

The difference between the bilayer and bulk BADs can be rationalized as follows. The mirror symmetry relationship between the top and bottom layers of the bilayer means that ions of the same charge sit on top of one another perpendicular to the plane containing the bilayer. As a result, the (repulsive) like-like electrostatic interactions are effectively maximized, leading to relatively acute Si-O-Si bond angles centered about the oxygen ions which bridge the two layers, and resulting in the peak at $\sim 175^\circ$. A simple geometric argument indicates that the presence of these relatively acute angles has a knock-on effect for the Si-O-Si angles centered about the oxygen ions which are in one of the bilayer planes, which will be relatively acute. This is an area that needs more study as there will always be a competition between the preferred Si-O-Si angles from chemistry and the requirements of the network topology. This effect will influence whether similar vitreous bilayers can be made from germanium and also whether aluminum ions can be alloyed with silicon ions in these vitreous silica bilayers.

Figure 6(b) shows the Si-Si-Si bond angle distributions obtained using the harmonic and the TS potential at the same densities as in Fig. 6(a). The results are compared to the C-C-C BAD generated from the original a-G configuration. Recall...
TABLE II. Variances in the position of the oxygen atoms perpendicular to the bilayer plane, $\Delta z$, for the 400 and 864 SiO$_2$ molecule configurations determined using both the harmonic and TS potentials at the reduced areas indicated. The oxygen atoms sit in three layers: upper, lower, and central. The small variances for the atoms in the central plane (of the order of the numerical error associated with the calculation), coupled with the identical variances of the atoms above and below this plane, are indicative of the existence of a mirror plane containing the central oxygen atoms.

that for crystalline graphene the bond angle is $\theta \sim 120^\circ$. The bilayer BADs show a sharp peak at $\theta \sim 90^\circ$ which corresponds to Si-Si-Si triplets in which the Si atoms are split between the two layers comprising the bilayer, while the higher broader peak corresponds to in-plane Si. The harmonic and TS potentials show similar distributions which are significantly broader than the a-G distribution.

To quantify the presence of a mirror plane after relaxation, which does not impose any symmetry, we determine the variance of the oxygen atom positions ($\Delta z$) perpendicular to the bilayer plane. The oxygen atoms can be considered as sitting in three distinct quasi-planes corresponding to the central layer (which joins the two original monolayers) and the two layers above and below this central layer. Table II lists the variances for the 400 and 864 SiO$_2$ molecule systems obtained using the harmonic potential (at two densities) and the TS (in the respective energy minima densities). The central atoms are clearly confined to a single plane while the atoms in the upper and lower layers show identical variances. The existence of the mirror plane is confirmed by determining the variance in the positions of the mirrored atoms in the upper and lower planes which is $\sim 0$ to within the numerical precision used. In principle the mirror symmetry can be broken once the potential contains Coulomb terms, etc., as the argument given in the section “Symmetry Plane” based on constraints does not hold with more complex forces. However in practice it seems these deviations are very small, although in principle present. We also note that this symmetry in the $\Delta z$ perpendicular to the bilayer plane holds not only at the macroscopic (average) level, but also at the local level between corresponding atoms above and below the central symmetry plane.

The most important results of this section, and the paper, are summarized in Fig. 7, where the flexibility windows and corresponding energy minima for the two amorphous and one crystalline sample are shown. It should be noted that the TS minimum lies within the flexibility window, as expected. In addition it lies towards the high area end of the window, reminiscent of the relationship observed in 3d zeolites. The argument given for the zeolites was that Coulomb inflation in the pores between the negative oxide ions caused the sample to swell to be very close to the maximum allowed while remaining inside the flexibility window. Such an argument cannot be given here, as there are no large pores as in zeolites, but we propose that Coulomb inflation, between the oxide ions, may still be the explanation within the rings of the bilayer. The silicon ions are less important as they are smaller. However we do not find this argument entirely convincing, and more work on understanding the subtleties of the effects of Coulomb interactions in ionic framework structures is needed.

V. SYMMETRY PLANE

The existence of a symmetry plane in an amorphous sample is surprising and quite unlike anything that we have encountered before. This symmetry emerges from the disordered state as the network takes advantage of the larger conformational space available when a symmetry plane is present compared to without. Hence symmetry is induced in a system which at first sight seems a canonical example of a system without symmetry. The argument for it is compelling as outlined here, and confirmed both by detailed atomic computer modeling and by experiment. Of course the individual tetrahedral units are close to perfect tetrahedra because of the strong local chemical bonding, but these pack in a disordered way. The local symmetry of perfect tetrahedra is not necessary for the argument for the symmetry plane to hold. Residual degrees of freedom in a structural unit are often referred to as floppy modes.

Consider two tetrahedral units (which we will call a tetrahedral pair) with a common oxygen atom, that is, Si$_2$O$_7$, as shown in Fig. 8. There are $N$ such units made from the $2N$ units of SiO$_2$ in the bilayer structure. A rigid body has 6 degrees of freedom in three dimensions, and for any two vertices of adjacent tetrahedra to coincide requires 3 constraints ($x_1 = x_2$, $y_1 = y_2$, and $z_1 = z_2$, where 1 and 2 refer to the two tetrahedral vertices that come together). We now give counting arguments for the case without symmetry and then with symmetry between the bilayers from a (proposed) reflection plane in the middle of the two layers.
two tetrahedra is, in general, not straight. Oxygen ions shown as small red spheres at the vertices and a silicon upper layer and one from the lower layer. Each tetrahedron has four triangles. There are 3N degrees of freedom and 3 \times N/2 constraints giving no remaining degrees of freedom. That is, such a network (example is a kagome lattice) is isostatic and only flexible if there is a surface and hence \(O(\sqrt{N})\) floppy modes. Now consider a 3d flexible monolayer framework of tetrahedra connected with the same 2d topology of corner-sharing triangles (each tetrahedron has three connected corners); then there are 6N degrees of freedom and 3 \times N/2 constraints giving a macroscopic number of degrees of freedom 3N/2. If further, the remaining vertex of each tetrahedron is positioned in a plane, so fixing one of its Cartesian coordinates, then the total number of degrees of freedom per tetrahedron is N/2. Adding the reflected monolayer to the original monolayer gives 2N SiO\(_2\) units with N/2 degrees of freedom for the bilayer, as before.

Note that these arguments apply to tetrahedra of arbitrary shape and size, so if there are some Al ions within tetrahedra in the lower layer at some composition, they should be mirrored in the upper layer based on the arguments in this section, although Coulomb repulsions between them would discourage this. Aluminum and silicon tetrahedra are both nearly perfect and isotactic,12 but have different sizes12 and so attempting to construct such bilayers would be something interesting to try experimentally. The situation is very different in conventional zeolites, where Loewenstein’s empirical rule22 for aluminosilicates states that (in essence) every Al-containing tetrahedra must be connected to four neighboring silicon-containing tetrahedra. It is possible, therefore, that Loewenstein’s rule could sometimes be violated in bilayer structures.

VI. CONCLUSIONS

We have shown how the recently discovered vitreous silica bilayer can be computer-modeled by progressive assembly, starting from an amorphous graphene sheet, and making various decorations and then relaxation with appropriate potentials. This pathway is of course not physical, but represents a convenient way of computer-generating such structures.

This system is probably the first network glass where the ring structure can be experimentally observed directly by STM and STEM measurements with atomic resolution, making it a paradigm system for future study. This present study provides a complementary computer-theoretical study that we hope will encourage further experimental and theoretical work.

An interesting observation is the unexpected mirror symmetry plane through the center of the bilayer, which seems to...
defy the logic which says that such bilayers should pucker. The fact that the top monolayer lies exactly on top of the lower monolayer means that a single layer is seen in the experimental STEM image, making structural interpretations much easier, and confirming the symmetry argument given here. This is a very unusual situation of a symmetry induced in a disordered system. However it should be noted that such a reflection symmetry is also expected in crystalline silica bilayers, where it is less surprising. Although additional terms in the potential, such as the Coulomb terms, may result in this symmetry being broken, this is not observed in the experiments, or in the computer simulations, at the current level of accuracy. It should be noted that amorphous graphene shows no such symmetry and is expected to show considerable puckering, unless constrained from doing so by a sufficient applied tension.\textsuperscript{11}

**ACKNOWLEDGMENTS**

We should like to thank Mike Treacy for many useful discussions including those relating to Loewenstein’s rule, and the US National Science Foundation for support under Grant No. DMR-0703973. We should also like to thank Hans-Joachim Freund and Markus Heyde for useful discussions and Pinshane Huang and David Muller for sharing their experimental data. D.S. acknowledges support from the Leverhulme Trust through an Emeritus Research Fellowship.
